

Assistive Collision Avoidance for Quadrotor Swarm Teleoperation

Dingjiang Zhou¹ and Mac Schwager²

Abstract—This paper presents a method for controlling quadrotor swarms in an environment with obstacles, with an intuitive human-swarm interface operated by a single human user. Our method allows for the quadrotor swarm to maintain a desired formation, while also keeping the quadrotors a safe distance from obstacles and from one another. We use a Virtual Rigid Body abstraction to provide a bridge between the single human user and the quadrotor swarm, so that a human user can fly an arbitrarily large quadrotor swarm from a single joystick. By applying multiple vector fields, collisions are automatically avoided within the swarm of quadrotors, and between the quadrotors and obstacles, while the Virtual Rigid Body is controlled by the human user. Our method is demonstrated in hardware experiments with groups of quadrotor micro aerial vehicles teleoperated by a single human operator in a motion capture system.

I. INTRODUCTION

In this paper, we propose a teleoperation architecture for a single human user to control an arbitrarily large swarm of quadrotors through a cluttered environment with a standard gaming joystick. The user controls the whole swarm as a single body, while local formation control and collision avoidance are taken care of autonomously by each robot. By allowing the quadrotors to autonomously avoid collisions, the human user can focus on the overall maneuver of the swarm, instead of taking care of each quadrotor to avoid the obstacles in the environment. Our approach can be useful in security, surveillance, and search and rescue applications, in which a human operator must maneuver a swarm through, e.g., a cluttered building, a forest, or a disaster site. Based on the abstraction of a *Virtual Rigid Body* (VRB) proposed in our previous work [1], we implement an intuitive human-swarm interface with a standard gaming joystick to fly a quadrotor swarm from a single human user. Our assistive collision avoidance algorithm supplements the quadrotor swarm control, so that the maneuver of the swarm is not interrupted by the obstacles. Our strategy is integrated with differential flatness-based control techniques, which have been used in the past primarily to design controllers for single quadrotors to execute agile trajectories [2], [3].

Our first idea is to control the group of quadrotors as a single body with a standard gaming joystick, in the framework of Virtual Rigid Body. The VRB allows us to decouple the trajectory of the whole swarm from the trajectories of the individual quadrotors within the swarm, and allows us to

generate the trajectory of the whole swarm from a joystick in real time. As long as the smoothness requirement of the trajectory is satisfied in SE(3), each quadrotor computes its own dynamically feasible SE(3) trajectory based on the differential flatness property of its dynamics. Our second idea is to let the collision avoidance be achieved automatically during the flight such that the human user will not be overwhelmed by controlling each single quadrotor to avoid colliding to the obstacle, and one another. Inspired by our previous work [3], we apply multiple vector fields for the obstacles, and also for the quadrotors, in order to keep a desired formation, as well as to avoid collision with the obstacles.

There exists an extensive literature in formation control. For example, [4], [5] proposed a formation control strategy in which a leader quadrotor flies an agile trajectory while other follower quadrotors control themselves to keep a desired formation. In [6], the authors achieved formation control for a team of quadrotors using only onboard vision. In [7], tools for trajectory generation and micro quadrotor swarm control with different formations were described. Also in [8], the authors shown the methods to display 3D features, as well as animations, with multiple aerial vehicles. Teleoperation of mobile robot swarm is considered in [9], [10], where multiple non-holonomic vehicles were controlled in a leader-follower formation and the leader robot was remotely driven to a desired velocity. In [11], a haptic interface is used to control the formation of a group of quadrotors. Gesture based human-swarm interaction is seen in [12], in which authors deciphered human gestures to drive multiple ground mobile robots to show different faces. Obstacle avoidance for single and multiple quadrotors is also heavily researched in the literature. For a single quadrotor, control through a haptic interface control is demonstrated in [13] where the pilot received force feedback when obstacles are close, and in [14] the authors proposed an approach to construct a novel dynamic kinesthetic boundary (DKB) to aid a pilot to navigate an aerial robotic vehicle through a cluttered environment. In [15], the authors provided a method to assist the operator to fly a quadrotor to perform collision avoidance by predicting its future trajectory. The paper [16] presents a method to assist the teleoperation of a quadrotor by constructing the nearby environment using sonar sensors. For multi-quadrotor scenarios, [17] and [18] employed mixed-integer linear program (MILP), and mixed-integer quadratic programming (MIQP), respectively, to generate optimal trajectories for aircrafts to avoid collision.

Our work is different from the above works in two aspects. Firstly, we apply our VRB abstraction such that the human-swarm interface is naturally integrated in our control. Secondly, our assistive collision avoidance algorithm

is applied to the swarm instead of a single quadrotor in real time, makes it directly applicable to a real-world setting, assuming the quadrotors have an adequate perception of their surroundings.

The remainder of this paper is organized as follows. The quadrotor dynamics and our Virtual Rigid Body abstraction, are presented in Section II. In Section III, we introduce our intuitive human-swarm interface which is used to control a quadrotor swarm from a single joystick. Our vector field based assistive collision avoidance algorithm is then introduced in Section IV. and our experiments with multiple KMe1 Nano Plus quadrotors, controlled from an off-the-shelf joystick, are seen in Section V. Our concluding remarks is finally shown in Section VI.

II. PRELIMINARY

In this section, we give a necessary background on quadrotor dynamics, and our Virtual Rigid Body abstraction.

A. Quadrotor Dynamics

A quadrotor is well-modeled as a rigid body with forces and torques applied from the four rotors and gravity [2]. The relevant forces, moments, and coordinate frames are shown in Figure 1.

Fig. 1. Coordinate frames of a quadrotor. The global reference frame is denoted by \mathcal{F}_w , and the quadrotor body-fixed frame is denoted by \mathcal{F}_b .

We define a global reference frame \mathcal{F}_w with a North-East-Down system, and have a body-fixed frame \mathcal{F}_b attached to the quadrotor, with its origin aligned at the center of mass. The orientation of the quadrotor is defined by the rotation matrix \mathbf{R} , parameterized with ZYX Euler angles, i.e., roll ϕ , pitch θ and yaw ψ [1]. The quadrotor dynamics are given by the nonlinear equations

$$\begin{cases} \dot{\mathbf{v}} = \mathbf{g} + \frac{1}{m}\mathbf{R}\mathbf{f}, & (1) \\ \dot{\mathbf{R}} = \mathbf{R}\boldsymbol{\Omega}, & (2) \\ \dot{\boldsymbol{\omega}}_b = \mathbf{J}^{-1}\boldsymbol{\tau} - \mathbf{J}^{-1}\boldsymbol{\Omega}\mathbf{J}\boldsymbol{\omega}_b, & (3) \\ \dot{\mathbf{p}} = \mathbf{v}, & (4) \end{cases}$$

where $\mathbf{v} = [v_x, v_y, v_z]^T$ is the global velocity, $\mathbf{g} = [0, 0, g]^T$ is the acceleration of gravity, m is the mass, and $\mathbf{f} = [0, 0, f_z]^T$ is the total thrust force generated from the rotors. The rotation matrix \mathbf{R} is defined with Euler angles ϕ , θ and ψ . The angular velocity of the quadrotor, $\boldsymbol{\omega}_b = [\omega_x, \omega_y, \omega_z]^T$, is expressed in the body frame \mathcal{F}_b , and $\boldsymbol{\Omega} = \boldsymbol{\omega}_b^\wedge = [0, -\omega_z, \omega_y; \omega_z, 0, -\omega_x; -\omega_y, \omega_x, 0]$. The torque generated from the rotors on the quadrotor is given

by $\boldsymbol{\tau} = [\tau_x, \tau_y, \tau_z]^T$, expressed in \mathcal{F}_b . The inertia matrix of the quadrotor is \mathbf{J} , and $\mathbf{p} = [x, y, z]^T$ is the global position of the quadrotor. The quadrotor's inputs are the total thrust and the three torques, $\boldsymbol{\mu} = [f_z, \tau_x, \tau_y, \tau_z]^T$, which is in four dimensions, and the system has a 12 dimensional state, i.e., $\boldsymbol{\xi} = [x, y, z, v_x, v_y, v_z, \psi, \theta, \phi, \omega_x, \omega_y, \omega_z]^T$.

Planning a trajectory to be executed by a quadrotor is not trivial, as one must find the states and inputs that satisfies the dynamics (1)–(4). We call a trajectory that satisfies the dynamics of a quadrotor for some input dynamically feasible, which is defined formally as follows.

Definition 1: (Dynamically Feasible Trajectory) A quadrotor trajectory $\boldsymbol{\xi}(t)$ is called dynamically feasible over a time interval $[t_1, t_2]$ if there exists a control input $\boldsymbol{\mu}(t)$ such that $\boldsymbol{\xi}(t)$ and $\boldsymbol{\mu}(t)$ satisfy (1)–(4) for all $t_1 \leq t \leq t_2$.

Differential flatness [19], [20] is a property of some nonlinear control systems that greatly simplifies the problem of finding dynamically feasible trajectories. Quadrotor dynamics are known to be differentially flat [1], [2], hence one can plan an arbitrary trajectory for the flat outputs (as long as it is sufficiently smooth), and analytically find a dynamically feasible trajectory, as well as the control inputs required to execute that trajectory. The key tool from differential flatness is called the *endogenous transformation* [19]. The endogenous transformation for quadrotor dynamics can be found in [1], [2], which maps the flat outputs $\boldsymbol{\sigma} = [x, y, z, \psi]^T$ of a quadrotor to its 12 dimensional states $\boldsymbol{\xi}$ and 4 dimensional control inputs $\boldsymbol{\mu}$.

B. Virtual Rigid Body

The concept of Virtual Rigid Body is defined in our previous work [1]. Consider a swarm of N robots labeled by $\{1, 2, \dots, N\}$, let \mathcal{F}_i denote the local reference frame of robot i , and we denote by $\mathbf{p}_i(t) \in \mathbb{R}^3$ the position, and $\mathbf{R}_i(t) \in SO(3)$ the orientation of robot i with respect to \mathcal{F}_w , at time t .

Definition 2 (Virtual Rigid Body): A Virtual Rigid Body is a group of N robots and a local reference frame \mathcal{F}_v , in which the local positions of the robots are specified by a set of potentially time-varying vectors $\{\mathbf{r}_1(t), \mathbf{r}_2(t), \dots, \mathbf{r}_N(t)\}$.

An example of a Virtual Rigid Body of three robots is shown in Figure 2, in which the *formation* and *transformation* are defined as follows.

Definition 3 (Formation): A formation $\boldsymbol{\Pi}$ is a Virtual Rigid Body with constant local positions $\{\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N\}$ in \mathcal{F}_v for a group of N robots with a time duration $T_{\boldsymbol{\Pi}} > 0$.

Definition 4 (Transformation): A transformation $\boldsymbol{\Phi}$ is a Virtual Rigid Body with time varying local positions $\{\mathbf{r}_1(t), \mathbf{r}_2(t), \dots, \mathbf{r}_N(t)\}$ in \mathcal{F}_v for a group of N robots with a time duration $T_{\boldsymbol{\Phi}} > 0$.

Let $\mathbf{p}_v(t) \in \mathbb{R}^3$ and $\mathbf{R}_v(t) \in SO(3)$ denote the position and orientation of the origin of \mathcal{F}_v in \mathcal{F}_w at time t , respectively. Since robots' positions are defined locally in the Virtual Rigid Body as in Definition 2, the relationship between $\mathbf{p}_i(t)$ and $\mathbf{r}_i(t)$ for robot i is described as $\mathbf{p}_i = \mathbf{p}_v + \mathbf{R}_v \mathbf{r}_i$, $i \in \{1, 2, \dots, N\}$, where “(t)” is dropped for simplicity.

Fig. 2. The concept of a VRB with a group of three robots. The VRB is in a formation Π_m when $t_m < t \leq t_{m+1}^m$, and Π_{m+1} when $t_{m+1} < t \leq t_{m+2}^{m+1}$. It is in a transformation Φ_{m+1}^m when $t_{m+1}^m \leq t \leq t_{m+1}$.

We define the trajectory of a Virtual Rigid Body to be the position and orientation of \mathcal{F}_v as a function of time, i.e., $\delta_v(t) = (\mathbf{p}_v(t), \mathbf{R}_v(t)) \in \mathcal{C}^4 : \mathbb{R}_{\geq 0} \mapsto \mathbb{R}^3 \times SO(3)$.

An example of the VRB trajectory $\delta_v(t)$ is also shown in Figure 2, depicted as a black dashed line. In correspondence, the trajectory of robot i in \mathcal{F}_w is denoted by $\delta_i(t) = (\mathbf{p}_i(t), \mathbf{R}_i(t)) \in \mathcal{C}^4$. In Figure 2, the trajectories for the three robots are depicted in red, blue and green dashed lines, respectively.

III. INTUITIVE HUMAN INTERFACE

Here we describe the human-swarm interface component of our control architecture. With our human-swarm interface, the human operator is able to control an arbitrarily large quadrotor swarm as if the swarm were a single aircraft. Our Virtual Rigid Body, which abstracts the quadrotor swarm as a single body, decouples the trajectory generation for a group of robots into two subproblems, (i) generating the trajectory of the VRB in the global reference frame \mathcal{F}_w , and (ii) generating the trajectory for each individual quadrotor within the VRB local reference frame \mathcal{F}_v . Our human-swarm interface hence solves the first subproblem, by means of generating a trajectory for the Virtual Rigid Body from a standard off-the-shelf joystick. The second subproblem, however, is solved with a formation library [1], which stores a set of formations, as well as transformations between any pair of formations, for the Virtual Rigid Body.

The joystick gives commands to our base computer, which interprets the commands as a state trajectory for the Virtual Rigid Body, then the commanded VRB state is broadcast to the quadrotors. This control method is intuitive, since the joystick is widely used in flight simulators and computer games. The goal of this section is to describe the map between the joystick signal, namely, Euler angles and thrust $(\phi_J, \theta_J, \psi_J, f_J)$ and their first derivatives $(\dot{\phi}_J, \dot{\theta}_J, \dot{\psi}_J, \dot{f}_J)$, to the Virtual Rigid Body trajectory $\delta_v(t)$ in real time.

The raw data from the joystick is noisy due to unavoidably jerky motion from the human hand, hence we apply a first order low pass filter to smooth this signal. Notice that the roll ϕ_J , pitch θ_J and yaw rate $\dot{\psi}_J$ are from the joystick directly, so that the roll rate $\dot{\phi}_J$ and the pitch rate $\dot{\theta}_J$ are obtained by numerical differentiation from ϕ_J and θ_J , while the yaw ψ_J is integrated from $\dot{\psi}_J$ numerically. Also, $\ddot{\psi}_J$ is from $\dot{\psi}_J$ by numerical differentiation.

We impose virtual dynamics on the Virtual Rigid Body to map the joystick commands to a VRB trajectory. The VRB dynamics can be as simple as possible, since there is no inherent physical dynamic constraints. In this paper, we let the VRB have single integrator dynamics,

$$\dot{\mathbf{x}}_v = \mathbf{v}, \quad (5)$$

where the state is $\mathbf{x}_v = [\mathbf{p}_v^T, \psi_v]^T$ – we set roll ϕ_v and pitch θ_v to zero. With this model, the VRB trajectory $\delta_v(t)$ is simplified as the position trajectory $\mathbf{p}_v(t)$ with the yaw trajectory $\psi_v(t)$. We apply again a first order filter to the input \mathbf{v} in (5),

$$\dot{\mathbf{v}} = -a\mathbf{v} + \mathbf{u}_1, \quad (6)$$

where a is a positive parameter, and the input \mathbf{u}_1 is from the joystick by $\mathbf{u}_1 = [e_1\theta_J \ e_1\phi_J \ e_2f_J \ e_3\dot{\psi}_J]^T$ in real time, where e_1 , e_2 and e_3 are positive constant scaling factors, such that e_1 and e_2 scale the spatial speed, and e_3 scales the yaw rate. The three scaling factors, along with the positive parameter a in (6), can be used as four variables for tuning the aggressiveness of the maneuver, and for avoiding the actuator saturation.

From (5) to (6), we obtain the VRB position trajectory $\mathbf{p}_v(t)$, yaw angle trajectory $\psi_v(t)$, as well as its velocity $\mathbf{v}_v(t)$. However, we require that the Virtual Rigid Body to be four times continuously differentiable (in \mathcal{C}^4) in order to use differential flatness based control tools. Therefore, the VRB acceleration $\mathbf{a}_v(t)$, jerk $\mathbf{j}_v(t)$ and snap $\mathbf{s}_v(t)$ must be found from the joystick commands. Similar to (6), we apply a first order filter to the acceleration, $\dot{\mathbf{a}}_v = -a\mathbf{a}_v + \mathbf{u}_2$, where the input \mathbf{u}_2 are from the joystick by $\mathbf{u}_2 = [e_1\ddot{\theta}_J \ e_1\ddot{\phi}_J \ e_2\ddot{f}_J]^T$. Finally, we obtain jerk and snap directly by

$$\mathbf{j}_v = \dot{\mathbf{a}}_v, \quad \mathbf{s}_v = \dot{\mathbf{j}}_v. \quad (7)$$

In conclusion, (5)–(7) fully define the trajectory $\delta_v(t)$ for the Virtual Rigid Body. With the VRB trajectory $\delta_v(t)$, and the formation or transformation of the VRB from a formation library, one can apply the methods in our previous work [1] to find the trajectory for each quadrotor.

IV. ASSISTIVE COLLISION AVOIDANCE

In this section, we introduce the component of collision avoidance algorithm in our control architecture, as a supplementary of the previous human-swarm interface to assist the human user by autonomously avoiding collisions with obstacles. Using multiple interacting vector fields, which is similar to a potential field, the algorithm allows for the formation to deform enough to avoid collisions with obstacles, and relax back into the formation when far away from obstacles. One possible drawback of potential field-based methods is that the deadlocks may occur [9], [10], however, since the swarm is teleoperated by a human user in our case, this can be less of a problem. The user can see when a deadlock is occurring, and reactively maneuver the swarm to dislodge the quadrotors that are stuck in a local minimum.

Our algorithm for collision avoidance is applied to environments like the scenario shown in Figure 3(a), in which a swarm of five quadrotors is under control from a human user,

while the environment contains two obstacles. The obstacles are modeled as cylinders with different radii. Since we focus on formation control and collision avoidance, we assume that the robots sense their local environment precisely.

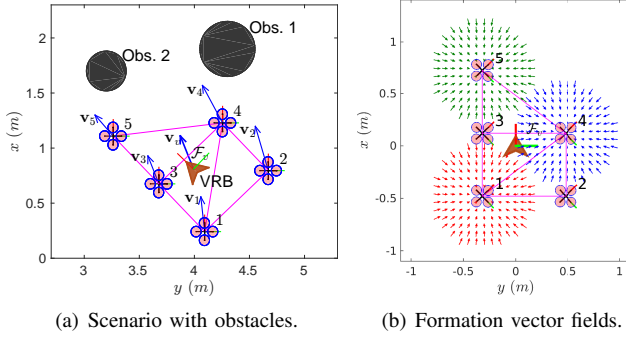

Fig. 3. (a), Top view of a scenario with two obstacles in the environment. The magenta lines show the connectivity of the quadrotor swarm. The orange arrowhead shape in the middle denotes the VRB, and the \mathbf{v}_v depicted by a thick blue arrow is the commanded velocity of the VRB from the joystick. The velocity of all quadrotors are denoted as \mathbf{v}_1 to \mathbf{v}_5 , respectively. (b), Formation vector fields for quadrotor 1, 4 and 5 in the VRB frame \mathcal{F}_v .

In our strategy, the obstacles affect the maneuver of the quadrotor swarm in two different ways. First, the obstacles influence the commanded velocity \mathbf{v}_v , as well as the commanded acceleration \mathbf{a}_v of the VRB through a vector field, such that the VRB will slow down or change its heading direction when there is an obstacle in its path. Second, the obstacles influence the individual quadrotors that are close to it, also through vector fields, that each individual quadrotor takes its own action to deviate from its original heading direction in order to avoid collision to these obstacles. Additionally, to avoid inter-vehicle collision, each quadrotor considers all the other quadrotors as dynamical obstacles with repelling vector fields.

Our control algorithm for collision avoidance runs in real time and is distributed among the quadrotor swarm, with the exception of the component that acts on the VRB, as described below. We apply the vector field method from our previous work [3], in which it was applied for a single quadrotor to avoid a static “virtual” obstacle in the environment. With running this control algorithm, the dynamical feasible trajectory of each quadrotor described in Definition 1, and the smoothness requirement of the states and inputs, can be satisfied.

A. Formation Vector Fields

In our VRB framework, we apply a vector field for each quadrotor in the VRB local frame \mathcal{F}_v , such that when the quadrotor deviates from its desired position, a forcing vector will act on the quadrotor to pull it back to the desired position. Here we take advantage of our VRB abstraction, so that instead of considering the maneuver of the quadrotors in the global frame, we only consider their maneuver in the VRB local frame.

Let the desired position of quadrotor i in the VRB local frame \mathcal{F}_v be denoted as \mathbf{r}_i^d , then the vector in the vector field at position \mathbf{r} for quadrotor i is defined as

$$\mathbf{V}_{0,i}(\mathbf{r}) = A(\mathbf{r}_i^d - \mathbf{r}), \quad i = 1, 2, \dots, N, \quad (8)$$

where A is a positive constant parameter. As long as the quadrotor can follow its vector field, it will eventually converge to its desired position in the VRB local frame, when the environment is obstacle free.

An example of a 2D version of this vector field for each quadrotor is shown in Figure 3(b), in which different color denotes the vector field for different quadrotor. Note that all five vector fields actually act on the quadrotor at once.

B. Vector Fields from Obstacles

Our collision avoidance algorithm works at two levels: The first level is that we generate a vector field to force the Virtual Rigid Body to change its commanded velocity \mathbf{v}_v to decrease the aggressiveness of the VRB, and the second level is that we generate another vector field from each obstacle to achieve collision avoidance for each quadrotor, while the VRB is still tracking its trajectory. The two levels can be unequally responsible in achieving collision avoidance. For example, one can increase the influence of the first level and hence decrease that of the second level, such that the entire swarm can be far away from the obstacles while keeping a desired formation. However, we choose to let the second level to be more responsible for collision avoidance. By doing so, collision is avoided for the quadrotor swarm, while the formation is partially maintained.

In this paper, for any obstacle, we consider a bounding cylinder that encompasses the obstacle in order to generate a repelling vector field. Figure 4 shows our repelling vector field for the obstacles in the scenario of Figure 3(a).

Fig. 4. Left: vector field for the VRB. Right: vector field for quadrotors. Each vector field is generated from (9), or (11), with different parameters. The darker color means larger magnitude and the lighter color means smaller magnitude. Intuitively, the VRB, or each single quadrotor, will be pushed toward the light region and avoid the dark region.

1) *Vector Field for the Virtual Rigid Body:* We assume that the quadrotor swarm maneuvers in the horizontal plane only, so that climbing to a higher altitude to avoid the obstacles is not an option in our setting. We define a repelling vector pointing from the position of an obstacle to the VRB at horizontal coordinate $\bar{\mathbf{p}}$, with its magnitude to be a Gaussian-like function related to the position and radius of this obstacle, as well as the VRB heading direction. Assuming that there are n obstacles in the environment, and we denote the horizontal position of obstacle k in the global frame \mathcal{F}_w as $\bar{\mathbf{o}}_{w,k}$, then the overall repelling vector in the vector fields generated from the n obstacles at horizontal coordinate $\bar{\mathbf{p}}$ is

$$\mathbf{V}_1(\bar{\mathbf{p}}) = \sum_{k=1}^n f_k(\bar{\mathbf{o}}_{w,k}, r_k, \hat{\mathbf{v}}) \frac{\bar{\mathbf{p}} - \bar{\mathbf{o}}_{w,k}}{\|\bar{\mathbf{p}} - \bar{\mathbf{o}}_{w,k}\|}, \quad (9)$$

where the magnitude $f_k(\bar{\mathbf{o}}_{w,k}, r_k, \hat{\mathbf{v}})$ is a function of the obstacle position $\bar{\mathbf{o}}_{w,k}$, radius r_k and the VRB heading direction $\hat{\mathbf{v}} = \mathbf{v}_v / \|\mathbf{v}_v\|$:

$$f_k(\bar{\mathbf{o}}_{w,k}, r_k, \hat{\mathbf{v}}) = B_k \exp \left(-(\bar{\mathbf{p}} - \bar{\mathbf{o}}_{w,k})^T \Sigma^{-1} (\bar{\mathbf{p}} - \bar{\mathbf{o}}_{w,k}) \right),$$

where B_k is a positive scalar parameter related to the radius r_k of obstacle k . The value of B_k can be chosen so that the commanded velocity \mathbf{v}_v for the VRB can still overcome the largest repelling vector, since the VRB is virtual. The 2×2 matrix Σ is positive definite and it defines the major and minor axes of the dynamic Gaussian-like function by

$$\Sigma^{-1} = [\hat{\mathbf{v}}, \hat{\mathbf{v}}^\perp] \begin{bmatrix} \frac{1}{2\sigma_1^2} & 0 \\ 0 & \frac{1}{2\sigma_2^2} \end{bmatrix} [\hat{\mathbf{v}}, \hat{\mathbf{v}}^\perp]^T, \quad (10)$$

where $\hat{\mathbf{v}}^\perp$ is the perpendicular unit vector of $\hat{\mathbf{v}}$, and σ_1, σ_2 are the covariance variables. From (10) and Figure 4 (left), one can see that the VRB is repelled more from the obstacle if it is heading towards the obstacle directly, than if it is passing by the obstacles from the side, as shown in Figure 4 (right).

2) *Vector Field for Quadrotors*: We design a stronger vector field for the individual quadrotors than that for the VRB, such that when a quadrotor gets too close to an obstacle, the repelling vector is powerful enough to “push” the quadrotor away,

$$\mathbf{V}_2(\bar{\mathbf{p}}) = \sum_{k=1}^n \left(C_k \exp \left(-\frac{\|\bar{\mathbf{p}} - \bar{\mathbf{o}}_{w,k}\|^2}{2\sigma_3^2} \right) \right) \frac{\bar{\mathbf{p}} - \bar{\mathbf{o}}_{w,k}}{\|\bar{\mathbf{p}} - \bar{\mathbf{o}}_{w,k}\|}, \quad (11)$$

where C_k is again a positive scalar parameter related to the radius of obstacle k . The value of C_k must be chosen large enough to ensure collision avoidance.

The vector field \mathbf{V}_2 is shown in Figure 4 (right). Equation (11) is expressed in the global frame \mathcal{F}_w , while in our simulation of collision avoidance in Section IV-D, we express them in the VRB local frame \mathcal{F}_v by

$$\mathbf{V}_2(\bar{\mathbf{r}}) = \sum_{k=1}^n \left(C_k \exp \left(-\frac{\|\bar{\mathbf{r}} - \bar{\mathbf{o}}_{v,k}\|^2}{2\sigma_3^2} \right) \right) \frac{\bar{\mathbf{r}} - \bar{\mathbf{o}}_{v,k}}{\|\bar{\mathbf{r}} - \bar{\mathbf{o}}_{v,k}\|}, \quad (12)$$

where $\bar{\mathbf{r}}$ denotes the horizontal coordinate in \mathcal{F}_v , and $\bar{\mathbf{o}}_{v,k}$ is the horizontal position of obstacle k in \mathcal{F}_v . Equation (12) is obvious since $\|\bar{\mathbf{p}} - \bar{\mathbf{o}}_{w,k}\| = \|\bar{\mathbf{r}} - \bar{\mathbf{o}}_{v,k}\|$.

The magnitude of the vector \mathbf{V}_2 in the vector field of obstacle 1 in the VRB local frame can be seen in Figure 5.

C. Vector Fields from Quadrotors

Here we also consider inter-vehicle collision avoidance. With the two vector fields described in Section IV-B, the obstacle avoidance is achieved, as seen from our experiment in Section V. To ensure inter-vehicle collision avoidance, and similar to (12), we again apply the vector field method to each quadrotor in the VRB local frame \mathcal{F}_v ,

$$\mathbf{V}_{3,i}(\mathbf{r}) = \sum_{j \in \mathcal{N}_i} \left(D \exp \left(-\frac{\|\mathbf{r} - \mathbf{r}_j\|^2}{2\sigma_4^2} \right) \right) \frac{\mathbf{r} - \mathbf{r}_j}{\|\mathbf{r} - \mathbf{r}_j\|},$$

where \mathcal{N}_i denotes the neighbors of quadrotor i . The scale parameter D and covariance σ_4 can be tuned so that the

vector field from each quadrotor will not effect the other quadrotors when the swarm is in a desired formation.

D. Collision Avoidance Simulation in VRB Local Frame

In this section, we show the effectiveness of our vector fields described in previous sections in a simulation of a quadrotor swarm with collision avoidance.

By taking the advantage of the Virtual Rigid Body abstraction, instead of considering the static or dynamic obstacles in the global frame \mathcal{F}_w , we consider dynamic obstacles in the VRB local frame. The global maneuver of each quadrotor is fused from the local maneuver of each quadrotor in \mathcal{F}_v and the global maneuver of the VRB in \mathcal{F}_w [1]. When collision avoidance is achieved in \mathcal{F}_v , it is automatically achieved in the \mathcal{F}_w for the quadrotor swarm.

Figure 5 shows a sequence of snapshots in our simulation starting from the scenario shown in Figure 3(a). Because the simulation is shown in \mathcal{F}_v , only the obstacles and quadrotors appear to move, while the VRB center appears to be fixed. In simulation, we pre-planned the trajectories for the obstacles, plotted as gray lines. These trajectories are designed to be smooth, although they can be more complex in real-world.

Fig. 5. A sequence of snapshots in a simulation of collision avoidance for a quadrotor swarm, shown in \mathcal{F}_v . The velocities of the obstacles are plotted with thick blue arrows, and the velocities of the quadrotors are plotted with thin blue and thick red arrows (the red arrow is a summation of the thin blue arrows). The vector field generated from obstacle 1 is indicated by a gray shadow, and the vector field from quadrotor 3 is indicated by a red shadow. The formation vector field for quadrotor 1 is plotted with gray arrows, and it is static in \mathcal{F}_v , since its purpose is to “pull” quadrotor 1 back to a desired position.

V. EXPERIMENTS

Our assistive collision avoidance algorithm for the tele-operated quadrotor swarm is validated experimentally with a group of Nano quadrotors in an environment with two obstacles. The radii of the obstacles are $r_1 = 0.15m$ and $r_2 = 0.11m$, respectively. In the experiment, position and orientation for the quadrotors are obtained with an OptiTrack motion capture system running at 120Hz. Our experiments share the same code base with our previous work [1], [3] to fly the quadrotors. A video of our experiments is available at <http://sites.bu.edu/msl/vrb-obstacles/>.

A. Experiment I: Trapezoid Formation

Our first experiment is to control a swarm of five quadrotors flying a “Trapezoid” formation in the experimental arena with the two cylinder obstacles. The “Trapezoid” formation is designed in our formation library. The human user can choose the formation by pressing a button on the joystick. A six-frame sequence of this experiment is shown in Figure 6.

Fig. 6. A sequence of snapshots of experiment I. (a), The quadrotor swarm is initialized as a “Trapezoid” formation; (b), The quadrotor swarm significantly deforms while passing through obstacle 2 from two sides; (c), The corner of the “Trapezoid” formation is squeezed by obstacle 2; (d), One quadrotor comes close to obstacle 1, but with no collision.

B. Experiment II: Line Formation

The second experiment is the same with experiment I, except that the VRB has a transformation from a “Trapezoid” formation to a “Line” formation, and we control the quadrotor swarm in the “Line” formation through the obstacle area. Again, a few snapshots of the experiment video are shown in Figure 7.

Fig. 7. A sequence of snapshots of experiment II. (a), The VRB is in a transformation from the “Trapezoid” formation to a “Line” formation; (b), The “Line” formation is deformed by obstacle 1; (c), The quadrotor swarm has successfully passed through the two obstacles; (d), the quadrotor swarm is significantly deformed by obstacle 2.

VI. CONCLUSION REMARKS

In this paper, we proposed a method of teleoperation of quadrotor swarms from a single human user with a standard joystick, while the quadrotors autonomously avoid collision with obstacles and with each other. with an intuitive human-swarm interface, and thanks to the framework of a Virtual Rigid Body, we successfully apply multiple vector fields among the quadrotor swarm, to avoid collisions by compliantly deforming the formation. Our assistive collision avoidance algorithm is validated experimentally. In the future, we plan to adapt this method to work with on-board perception of the obstacles.
